Sand-and-gravel mining is Ohio’s second-largest (on a tonnage basis) mining industry. In 2012, 30.5 million tons (t) of sand and gravel were produced in Ohio, making it the sixth-largest sand-and-gravel producing state after California, Texas, Minnesota, Michigan, and Utah. Sand-and-gravel mining also is the second-largest nonfuel mining industry in the United States; national production of construction sand and gravel in 2012 was estimated to be 928 million t.

Sand and gravel are the only mineral resources to be produced in every state and are the most widely produced mineral resources in Ohio—84 of the state’s 88 counties have reported commercial sand-and-gravel production during the past 60 years. In 2012, Ohio had 213 reporting sand-and-gravel mines operating in 57 counties. The top ten sand-and-gravel producing counties, in decreasing order of production, in 2012 were Stark, Portage, Hamilton, Franklin, Butler, Tuscarawas, Greene, Meigs, Montgomery, and Washington. Together, these counties accounted for more than 65 percent of Ohio’s sand-and-gravel sales.

Sand and gravel were the last of Ohio’s mineral resources to be commercially exploited. State records for sand-and-gravel production began with 1904, when 1.4 million tons were reported to have been produced. Sand and gravel were not produced to any significant extent before 1900 because the primary applications for construction sand and gravel did not exist. Primary uses for sand and gravel in the early 1900s, as well as today, were aggregate for concrete and paving. At that time, wood-plank sidewalks were being replaced with concrete sidewalks; bridge and building foundations were being constructed of poured concrete rather than cut stone; and dirt roads began to be surfaced with aggregate to accommodate the newly invented automobile.

WHAT ARE SAND AND GRAVEL?

Sand and gravel are unconsolidated, natural accumulations of rounded rock and mineral fragments. Unlike other mineral resources, such as gypsum, salt, limestone, dolomite, clay, shale, and coal, which are defined on the basis of composition, sand and gravel are defined on the basis of particle size. Sand consists of rock or mineral particles ranging in size from 0.002 to 0.08 inches (in) in diameter, and gravel consists of particles ranging from 0.08 to 2.5 in in diameter. Geologists commonly further define sand and gravel and larger rock particles as grains (0.04–0.08 in), granules (0.08–0.16 in), pebbles (0.16–2.5 in), cobbles (2.5–10 in), and boulders (more than 10 in). Sand and gravel particles are eroded fragments of rock formations (and shell material in coastal and former coastal areas); thus their range of chemical and mineralogical composition is as variable as the rocks from which they are derived. Some of the more common rock and mineral compositions of sand and gravel particles in Ohio are limestone, dolomite, quartzite (derived from Sharon conglomerate), shale, sandstone, siltstone, chert, flint, quartz, coal, and a large variety of igneous and metamorphic rock and mineral types transported to Ohio from central Canada by Ice Age glaciers.

High-quality sand-and-gravel deposits in Ohio are composed mostly of hard, durable rock and mineral types, such as limestone, dolomite, quartzite, granite, diorite, greenstone, and quartz. Undesirable or deleterious constituents in sand-and-gravel deposits cause premature deterioration or disfiguration of the products (such as pavement, concrete blocks, and sidewalks) in which they are used. Some of the more common deleterious constituents in Ohio sand-and-gravel deposits include shale, friable sandstone, siltstone, coal, chert, claystone, and ironstone.

HOW ARE SAND-AND-GRAVEL DEPOSITS FORMED?

Most sand-and-gravel deposits in Ohio were formed directly or indirectly by continental glaciers, which occupied up to two-thirds of the state during the recent Ice Age, about 2.5 million years to 11,700 years before the present. Sand-and-gravel deposits formed directly by glaciers include kames and eskers. Kames are conical hills or short irregular ridges of stratified (layered) rock material transported by glaciers and deposited by glacial meltwater flowing along the margins of or within crevasses in melting glaciers. Kames are found throughout the glaciated portion of the state primarily in the Ohio River drainage system. The largest kame complex in Ohio occupies a 15-mile (mi)-wide by 50-mi-long corridor in portions of Geauga, Portage, Summit, and Stark Counties. Eskers are sinuous, linear ridges of stratified material deposited by meltwater streams flowing on, within, or below melting glaciers. In Ohio, eskers are much less common than kames. The state’s best developed esker is probably the 10-mi-long Circleville Esker, which occupies the central portion of the Scioto River valley in Pickaway County. Outwash is stratified drift deposited indirectly by glaciers in valleys or on plains by meltwater issuing from the front of a melting glacier. Outwash deposits are present in most river valleys connecting the glaciated portion of the state with the Ohio River. Outwash also is present along the Ohio River. The largest inland outwash deposits in Ohio are present along a 100-mi-long stretch of the Great Miami-Mad River system between Bellefontaine and Cincinnati and along a 90-mi-long stretch of the Scioto River valley between Columbus and Portsmouth.

Olen, Inc., sand-and-gravel quarry in south Columbus, Franklin County, showing conical stockpiles and several conveyer systems.
The method of choice for mining sand and gravel is primarily an artifical lake.

After removal from the ground, sand and gravel are transported by front-end loaders, trucks, or conveyors to a processing plant, where the material is washed, sieved for desired size gradations, and stored in conical stockpiles. In some instances, gravel particles are crushed before sieving in order to increase the amount of a desired particle-size fraction. Material is then removed from stockpiles using front-end loaders or conveyors and typically loaded into large dump trucks, which deliver the product to the job site. Before leaving the mine, the dump trucks pass over a scale, which weighs each load of sand and gravel. The scale master tallies the amount of material being hauled away by each buyer and provides that information to the mine’s business office, which generates invoices. While most sand and gravel mined in Ohio are transported by truck, some material also is moved by rail, river barges, and Great Lakes-class freighters.

Sand and gravel are sold by the ton (2,000 pounds). A ton of dry, loose sand or gravel has a volume of about 20 cubic feet. In 2012 in Ohio, a ton of sand and gravel sold for an average of $6.53 at the mine. Because sand and gravel are high-volume, low-value commodities, their costs are driven ultimately by transportation costs. In order to minimize aggregate-transportation costs, it is essential that aggregate be produced as close as possible to urban centers, where most aggregate is consumed. For this reason, forward-looking land-use planners and zoning officials use geologic maps to designate selected areas within their jurisdictions for future aggregate-mining development.

After mining, sand-and-gravel pits are among the least expensive mining sites to reclaim and commonly are converted into beautifully landscaped golf courses and attractive building sites for new houses. Postmining land values commonly exceed premining values because of terrain improvements and the creation of wetlands, lakes, and ponds for boating, fishing, and swimming.

HOW ARE SAND AND GRAVEL USED?

Sand and gravel are used primarily for aggregate—hard, nonreactive rock particles that can be characterized and marketed according to particle size, shape, hardness, soundness, and mineralogy. Aggregate is the most widely used mineral commodity in the United States and may be derived from natural deposits of sand and gravel or from crushing of quarry rock. The dominant use of sand and gravel is as construction aggregate in Portland-cement concrete and asphaltic concrete. Most building and bridge foundations are deposited as low-grade modern commercial buildings, most new interstate highways, and sidewalks are made of Portland-cement concrete. Asphaltic or bituminous concrete (blacktop) is the preferred paving material for many primary and secondary highways, parking lots, bike trails, and driveways and for repaving of concrete highways. Gravel aggregate commonly is used alone or with a binder (such as tar) to pave rural roads and as ballast for railroad tracks. Other construction uses of sand and gravel include fill material, drainage media, and filtration beds for water-treatment facilities. Industrial and other uses of Ohio sand include molding sand for castings in foundry operations, sandblasting abrasive, and traction enhancer for ice-covered highways and sidewalks.

Approximately 4 t of sand and gravel must be mined each year for every person in the United States. About 90 t of aggregate are required for a new six-room house; 15,000 t are required for an office building for every person in the United States. About 90 t of aggregate are required for a new six-room house; 15,000 t are required for an office building; 15,000 t are required for an average-size school; and 85,000 t are required for each mile of new four-lane highway.
